ABSTRACT

Multi-robot systems researchers have been investigating adaptive coordination methods for improving spatial coordination in teams. Such methods adapt the coordination method to the dynamic changes in density of the robots. Unfortunately, while their empirical success is evident, none of these methods has been understood in the context of existing formal work on multi-robot learning. This paper presents a reinforcement-learning approach to coordination algorithm selection, which is not only shown to work well in experiments, but is also analytically grounded. We present a reward function (*Effectiveness Index*, EI), that reduces time and resources spent coordinating, and maximizes the time between conflicts that require coordination. It does this by measuring *the resource-spending velocity*. We empirically show its success in several domains, including robots in virtual worlds, simulated robots, and physical AIBO robots executing foraging. In addition, we analytically explore the reasons that EI works well. We show that under some assumptions, spatial coordination opportunities can be modeled as matrix games in which the payoffs are directly a function of EI estimates. The use of reinforcement learning leads to robots maximizing their EI rewards in equilibrium. This work is a step towards bridging the gap between the theoretical study of interactions, and their use in multi-robot coordination.

1. INTRODUCTION

Multi-robot systems researchers have been investigating coordination methods for improving spatial coordination in teams [9, 18, 17]. Such methods attempt to resolve spatial conflicts between team-members, e.g., by dynamic setting of right-of-way priorities [20, 24], territorial separation [19, 7, 12], or role-based priorities [15]. It is accepted that no one method is always best [8, 6, 17], and that all methods reach a point where adding robots to the group (i.e., increasing the density of the robots in space) reduces overall productivity [19, 18].

There is thus growing interest in adaptive coordination approaches, which adapt the coordination method to the dynamic changes in density. Zuluaga and Vaughan adjust the right-away priorities based on the amount of local effort (or investment) by team-members [24]. Toledo and Jennings [6] propose an algorithm-selection approach, based on reinforcement learning, where fixed coordination methods are switched to accommodate dynamic changes to the environment.

More recently, Rosenfeld et al. [17] advocated allowing each robot to individually switch coordination methods to reduce its own estimated resource costs. In general, all of these adaptive coordination methods have demonstrated much success in multiple domains of interest.

Unfortunately, while their empirical success is evident, none of these methods have ever been analytically proven to work, nor understood in the context of existing formal work on multi-robot learning and adaptation. As a result, their optimality and the appropriate conditions for their use remain open questions. Put simply, they pose a puzzle: These are methods that work well in practice—both in simulations and with real robots—but the reasons for their success remain elusive.

This paper presents a reinforcement-learning approach to coordination algorithm selection, which is not only shown to work well in experiments, but also explored analytically. The reward function used as the basis for the learning is called *Effectiveness Index* (EI). The key idea in EI is to reduce time and resources spent coordinating, and maximize the time between conflicts that require coordination. It does this by measuring *the resource-spending velocity* (the resource "burn rate"). The use of reinforcement learning minimizes this velocity. One nice feature of EI is that it does not require any knowledge of the task involved, and is thus domain-independent.

We empirically and analytically evaluate the use of EI. We empirically show that EI succeeds in improving multi-robot coordination in several domains, including robots in virtual worlds, simulated robots, and physical AIBO robots executing foraging. In addition, we analytically explore the reasons and assumptions underlying this success. We formalize the experiment domains as extensive-form games. We show that under some assumptions, these games can be modeled as matrix games in which the payoffs to the robots are unknown, but are directly a function of EI estimates. The use of reinforcement learning leads to robots maximizing their EI rewards in equilibrium. We believe that this work represents a step towards bridging the gap between the theoretical study of interactions (via game theory), and their use to explain and inform multi-robot coordination.

2. RELATED WORK

Most closely related to our work is earlier work on adaptation based on coordination effort. Rosenfeld et al. [17], presented a method that adapts the selection of coordination methods by multi-robot teams, to the dynamic settings in which team-members find themselves. The method relies on measuring the resources expended on coordination, using a measure called Combined Coordination Cost (*CCC*); however, it ignores the gains accumulated from long periods of no coordination needs, in contrast to our work. Similarly to our work, the adaptation is stateless, i.e., has no mapping

from world state to actions/methods. Instead, the CCC is estimated at any given point, and once it passes pre-learned (learned offline) thresholds, it causes dynamic re-selection of the coordination methods by each individual robot, attempting to minimize the CCC. In contrast, all our learning and adaption is done on-line.

Vaughan et al. [20] presented a method called *aggression* for reducing interference in distributed robot teams. When robots come too close to each other, each of the robots demonstrate its own level of aggression such that the robot with the highest level becomes the winner, while the loser concedes its place. Later, Zuluaga and Vaughan [24] have shown that choosing aggression level proportional to the robot's task investment can produce better overall system performance compared to aggression chosen at random. This result is compatible with our findings. However, Effectiveness Index relies solely on task-independent resource measures.

Excelente-Toledo and Jennings [6] propose a mechanism for selecting between coordination methods, based on their effectiveness and importance. They define a number of general characteristics of coordination methods, including the conditions (and cost for achieving them) for the application of each method, the cost of the algorithm, and their likelihood of success. Each of these characteristics manually receives a qualitative grade (high, medium, low), during an offline evaluation period. During run-time, the cost of each coordination method (with the additional cost of achieving its application conditions), and the likelihood of success are used as the basis for selection. Similarly to this work, we utilize the concepts of method costs and success, though the process is automated, and measures these factors quantitatively *on-line*. Reinforcement learning is used as the basis for coordination method selection.

Most investigations of reinforcement learning in multi-robot settings have focused on improving the learning mechanisms (e.g., modifying the basic Q-learning algorithm), and utilized task-specific reward functions. We briefly discuss these below. Two recent surveys are provided in [23, 10].

Matarić [14] discusses several techniques for using rewards in multi-robot Q-learning: A local performance-based reward, a global performance-based reward, and a heuristic strategy referred to as shaped reinforcement; it combines rewards based on local rewards, global rewards and coordination interference of the robots. Balch [3] reports on using reinforcement learning in individual robot behavior selection. The rewards for the selection were carefully selected for each domain and application, in contrast to our work. In contrast to these investigations, we explore a domain-independent reward function, based on minimizing resource use, and use them in selecting between coordination methods, rather than task behaviors.

Wolpert et al. [22, 21] developed the COIN reinforcement-learning framework. Each agent's reward function is based on *wonderful life utility*, the difference between the group utility with the agent, and without it. Later work by Agogino and Tumer further extended this approach [1]. Similarly to these our study focuses on the reward function, rather than the learning algorithm; and similarly, we focus on functions that are *aligned* with global group utility. However, our work differs in several ways. First, we distinguish utility due to coordination, from utility due to task execution. Second, our reward function distinguishes also the time spent coordinating and time spent executing the task.

3. LIMITING RESOURCE SPENDING

We first cast the problem of selecting coordination algorithms as a reinforcement learning problem (Section 3.1). We then introduce the effective index (EI) reward function in Section 3.2.

3.1 Coordination Algorithm Selection

Multilateral coordination prevents and resolves conflicts among robots in a multi-robot system (MRS). Such conflicts can emerge as results for shared resource (e.g., space), or as a result of violation of joint decisions by team-members. Many coordination algorithms (protocols) have been proposed and explored by MRS researchers [7, 15, 19, 20]. Not one method is good for all cases and group sizes [17]. However, deciding on a coordination method for use is not a trivial task, as the effectiveness of coordination methods in a given context is not known in advance.

We focus here on loosely-coupled application scenarios where coordination is triggered by conflict situations, identified through some mechanism (we assume that such a mechanism exists, though it may differ between domains; most researchers simply use a pending collision as a trigger). Thus the normal routine of a robot's operation is to carry out its primary task, until it is interrupted by an occurring or potentially-occurring conflict with another robot, which must be resolved by a coordination algorithm. Each such interruption is called *a conflict event*. The event triggers a coordination algorithm to handle the conflict. Once it successfully finishes, the robots involved go back to their primary task. Such multi-robot scenarios include foraging, search and exploration, and deliveries.

Let $A = \{\ldots, a_i, \ldots\}, 1 \leq i \leq N$ be a group of N robots, cooperating on a group task that started at time 0 (arbitrarily) lasts up-to time T (A starts working and stops working on the task together). We denote by $T_i = \{c_{i,j}\}, 0 \leq j \leq K_i$ the set of conflict events for robot i, where $c_{i,j}$ marks the time of the beginning of each conflict.

The time between the beginning of a conflict event j, and up until the next event, the interval $I_{i,j} = [c_{i,j}, c_{i,j+1})$, can be broken into two conceptual periods: The *active* interval $I^a_{i,j} = [c_{i,j}, t_{i,j})$ (for some $c_{i,j} < t_{i,j} < c_{i,j+1}$) in which the robot was actively investing resources in coordination, and the *passive* interval $I^p_{i,j} = [t_{i,j}, c_{i,j+1})$ in which the robot no longer requires investing in coordination; from its perspective the conflict event has been successfully handled, and it is back to carrying out its task. By definition $I_{i,j} = I^a_{i,j} + I^p_{i,j}$. We define the *total active time* as $I^a = \sum_i \sum_j I^a_{i,j}$ and the *total passive time* as $I^p = \sum_i \sum_j I^p_{i,j}$.

Our research focuses on a case where the robot has a nonempty set M of coordination algorithms to select from. The choice of a specific coordination method $\alpha \in M$ for a given conflict event $c_{i,j}$ may effect the active and passive intervals $I^a_{i,j}, I^p_{i,j}$ (and possibly, other conflicts; see next section). To denote this dependency we use $I^a_{i,j}(\alpha)$,$I^p_{i,j}(\alpha)$ as active and passive intervals (respectively), due to using coordination method α. Figure 1 illustrates this notation.

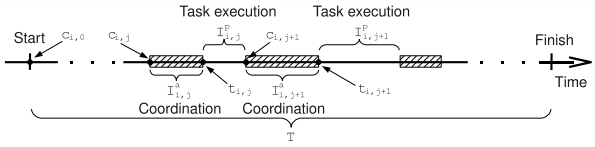

Figure 1: Illustration of task time-line, from the robots' perspective. Task execution is occasionally interrupted by the requirement to spend resources on coordination.

We define the problem of coordination algorithm selection in terms of reinforcement learning. We assume each robot tries to maximize its own reward by selecting a coordination method α. Typically, reward functions are given, and indeed most previous work focuses on learning algorithms that use the reward functions as efficiently as possible. Instead, we assume a very basic learning algorithm (a simple Q-Learning variant), and instead focus on defining a reward function (see below).

3.2 Effectiveness Index

We call the proposed general reward for coordination *Effectiveness Index* (EI). Its domain independence is based on its using three intrinsic (rather than extrinsic) factors in its computation; these factors depend only on internal computation or measurement, rather than environment responses.

3.2.1 The cost of coordinating. The first factor we consider is the cost of internal resources (other than time) used by the chosen method. This is especially important in physical robots, where battery life and power are a concern. We argue that such internal estimate of resource usage is practical:

- First, some resource usage is directly measurable. For instance, energy consumption during coordinated movement (e.g., when getting out of a possible collision) or communications (when communicating to avoid a collision) is directly measurable in robots, by accessing the battery device before and after using the coordination algorithm.
- Second, resource usage may sometimes be analytically computed. For instance, given a the basic resource cost of a unit of transmission, the cost of using a specific protocol may be analytically computed (as it is tied directly to its communication complexity in bits).
- Finally, the most general way is in using of a resources manager with capability to monitor resource usage by components of the robot system. The description of such a manager is beyond the scope of this work, though we note in passing that such managers exist already for general operating systems.

We denote by C_i^C the total cost of coordination, of robot i. It can be broken into the costs spent on resolving all conflicts $C_i^C = \sum_j C_{i,j}^C$. $C_{i,j}^C$ is similar to other measures suggested previously, but excludes the cost of time and resources spent before the conflict (unlike [17]), and is limited to only considering individual intrinsic resources (unlike [24]).

Let us use a cost function $cost_i(\alpha, t)$ to represent the costs due to using coordination method $\alpha \in M$ at any time t during the lifetime of the robot. The function is not necessarily known to us a-priori (and indeed, in this research, is not).

Using the function $cost_i(\alpha, t)$ we define the $C_{i,j}^C$ of a particular event of robot i at time $c_{i,j}$:

$$\begin{aligned} C_{i,j}^C(\alpha) &= \int_{c_{i,j}}^{t_{i,j}} cost_i(\alpha, t)\ \mathrm{d}t + \int_{t_{i,j}}^{c_{i,j+1}} cost_i(\alpha, t)\ \mathrm{d}t \\ &= \int_{c_{i,j}}^{t_{i,j}} cost_i(\alpha, t)\ \mathrm{d}t \end{aligned} \quad (1)$$

$C_{i,j}^C$ is defined as the cost of applying the coordination algorithm during the active interval $[c_{i,j}, t_{i,j})$ and the passive interval $[t_{i,j}, c_{i,j+1})$. However, the coordination costs during the passive interval are zero by definition.

3.2.2 The time spent coordinating. The main goal of a coordination algorithm is to reach a (joint) decision that allows all involved robots to continue their primary activity. Therefore, the sooner the robot returns to its main task, the less time is spent on coordination, and likely, the robot can finish its task more quickly. Thus, smaller I_i^a is better. Note that this is true regardless of the use of other resources (which are measured by C_i^C). Even if somehow other resources were free, effective coordination would minimize conflict-resolution time.

We thus define the *Active Coordination Cost* (ACC) function for robot i and method α at time $c_{i,j}$, that considers the *active time* in the calculation of coordination resources cost:

$$ACC_{i,j}(\alpha) \equiv I_{i,j}^a(\alpha) + C_{i,j}^C(\alpha) \quad (2)$$

3.2.3 The frequency of coordinating. If there are frequent interruptions to the robot's task in order to coordinate, even if short-lived and inexpensive, this would delay the robot. We assume (and the results show) that good coordination decisions lead to long durations of non-interrupted work by the robot. Therefore, the frequency of coordination method's use is not less important than the time spent on conflict resolving. Thus, larger $I_{i,j}^p$ is better.

We thus want to balance the total active coordination cost $ACC_i = \sum_j ACC_{i,j}$ against the frequency of coordination. We want to balance short-lived, infrequent calls to an expensive coordination method against somewhat more frequent calls to a cheaper coordination method.

We therefore define the Effectiveness Index of robot i, of conflict j, due to using coordination method $\alpha \in M$ as follows:

$$EI_{i,j}(\alpha) \equiv \frac{ACC_{i,j}(\alpha)}{I_{i,j}^a(\alpha) + I_{i,j}^p(\alpha)} = \frac{I_{i,j}^a(\alpha) + C_{i,j}^C(\alpha)}{I_{i,j}^a(\alpha) + I_{i,j}^p(\alpha)} \quad (3)$$

That is, the effectiveness index (EI) of a coordination method α during this event is the velocity by which it spends resources during its execution, amortized by how long a period in which no conflict occurs. Since greater EI signifies greater costs, we typically put a negation sign in front of the EI, to signify that greater velocity is worse; we seek to minimize resource spending velocity.

In this paper we use the simple single-state Q-learning algorithm to estimate the EI values from the robot's individual perspective. The learning algorithm we use is stateless:

$$Q_t(a) = Q_{t-1}(a) + \rho(R_t(a) - \gamma Q_{t-1}(a))$$

where ρ is the learning speed factor, and γ is a factor of discounting. The algorithm uses a constant exploration rate β.

4. EXPERIMENTS IN MULTIPLE DOMAINS

We now turn to briefly survey a subset of experiment results, in multiple domains, supporting the use of EI in multi-robot team tasks. Due to lack of space, we only provide representative results in each domain.

Foraging in TeamBots Simulation. Foraging is a canonical task in multi-robot systems research. Here, robots locate target items (pucks) within the work area, and deliver them to a goal region. As was the case in Rosenfeld et al.'s work [17], we used the TeamBots simulator [2] to run experiments. Teambots simulated the activity of groups of Nomad N150 robots in a foraging area that measured approximately 5 by 5 meters. We used a total of 40 target pucks, 20 of which were stationary within the search area, and 20 moved randomly. For each group, we measured how many pucks were delivered to the goal region by groups of 3,5,15,25,35,39 robots within 10 and 20 minutes. We averaged the results of 16–30 trials in each group-size configuration with the robots being placed at random initial positions for each run. Thus, each experiment simulated for each method a total of about 100 trials of 10 and 20 minute intervals.

We compare the EI method with random coordination algorithm selection (RND), and to the method of Rosenfeld et al. (ACIM) (which uses offline learning [17]). Each of these selection methods selectssss between three types of coordination methods (α), described also in [17]: Noise (which essentially allows the robots to collide, but increases their motion uncertainty to try to escape

collisions), Aggression [20] (where one robot backs away, while the other moves forward), and Repel, in which robots move away (variable distance) to avoid an impending collision.

Figures 2(a)–2(c) show a subset of results. In all, the X axis marks the group size, and the Y axis marks the number of pucks collected. Figure 2(a) shows that given no resource limitations, the EI method is as good as ACIM (and Repel) which provides the best results, though it has not used prior off-line learning. Figure 2(b) shows the advantage of EI over ACIM when resource costs apply. Here, when ACIM takes fuel costs into account, it performs well. But when it does not, its performance is very low. On the other hand, EI with fuel costs and without perform well. Finally, Figure 2(c) shows how ACIM and EI respond to unknown costs. Here, both EI and ACIM take fuel costs into account, but the actual fuel costs are greater. EI provides significantly better performance in these settings (1-tailed t-test, $p = 0.0027$).

Foraging in AIBO Robots. We have also utilized EI-based adaptation in foraging experiments with Sony AIBO robots, shown in Figure 3. Three robots were placed within a boxed arena, measuring 2m by 2m, and containing four pucks The robots were allowed up to 10 minutes to collect the pucks. We implemented two basic coordination methods: Noise and Repel (described above). We ran 8 trials of Noise, and 9 of Repel.

Figure 3: Three Sony AIBO robots executing a foraging task in our laboratory. The goal location is in the top left corner. Every puck collected was taken out of the arena.

We faced several challenges in applying EI to the robots. First, we found that the time-limit was not sufficient to allow EI to train. We thus allowed preliminary learning to take place, for approximately 15 minutes. The EI values at the end of this period (which were not optimal) were used as the initial values for the EI trials. Each of the ten trials started with these initial Q table values, and the Q updates continued from this point.

Second, the robots cannot detect conflicts with certainty. For instance, a robot bumping into the walled side of the arena would detect a conflict. Moreover, some collisions between robots cannot be detected, due to their limited sensing capabilities. We solved this by allowing the operator to initiate conflicts by a fixed procedure.

Finally, we found that sometimes robots failed catastrophically (i.e., suffered hardware shutoff). So as to not bias the trials, we measured the average time per puck retrieved.

We contrasted the performance of the three groups (Noise, Repel, and EI). Figure 4(a) shows the pucks collected per minute by each of the three methods (median). We found that Repel (selected by all three robots) is the best technique. The EI method did better than Noise, but did not reach the results of Repel. This is to be expected, because the EI algorithm utilized constant exploration rate (up 19% of the conflicts of each robot). Thus even under the best of conditions, the EI runs are expected to worse. We see the same trend in Figure 4(b), which shows the average number of conflicts in the different groups. We again see that the number of conflicts in learning is between Repel and Noise.

To show that indeed the fixed exploration rate had a significant contribution to the results, we also examine the EI-based rankings of the noise and repel methods (i.e., whether the EI values ultimately prefer repel or noise). Figure 4(c) shows the average EI values that were achieved at the end of each run. For each robot, we see two bars: One for the EI value of Repel, and one for Noise. We see that in all three robots, the EI values learned for Repel are better (lower). Thus left to choose based on the EI values, all robots would have chosen the Repel method (the optimal choice).

EI in Virtual Environments. Finally, we evaluated the use of EI with robots in virtual environments. Here, we utilized robots that operate in VR-Forces[13], a commercial high-fidelity simulator. Each robot controls a simulated entity in the environment, and must carry out its own path planning and decision-making.

Within this environment, we conducted experiments with four virtual robots, where the coordination was implicit, rather than explicit. All of the four robots had the goal of getting to a target location. They could do this through one of two paths, the first ($path1$) slightly shorter than the other ($path2$). Actual travel times through the paths vary, and are not just a function of the path length. First, when robots move on the same path, they sometimes crowd the path and cause delays in moving on it (e.g., if robots collide or block others from reaching a navigation point). Second, because this is a high-fidelity simulation, the actual movement velocity of the robots is not always the same, and varies slightly from one run to the next. The result is that it is not immediately obvious how robots should divide up the paths between them. Using EI to select between the paths is not a selection of a coordination method, but is instead a selection of a task, such that coordination is implicit.

We conducted 21 runs, where the EI values were saved from one run to the next. The results (Figure 5) show convergence of the first three robots to selecting $path1$, while the fourth and last robot jumps back and forth between $path1$ and $path2$. When we examine the results in detail, we discover that indeed the decision of the fourth robot is difficult: On one hand, four robots on $path1$ often interfere with each other. On the other hand, the use of $path2$ does add to the overall task time of the robot. Thus the EI values are very close to each other, and the robot in fact converges to arbitrary selection between the two paths.

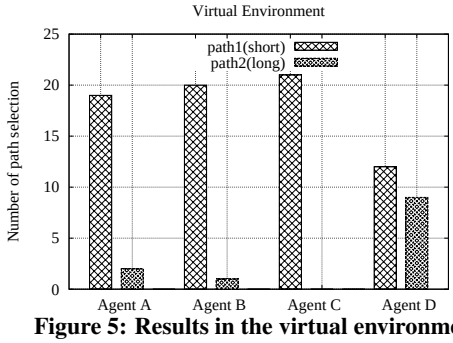

Figure 5: Results in the virtual environment domain.

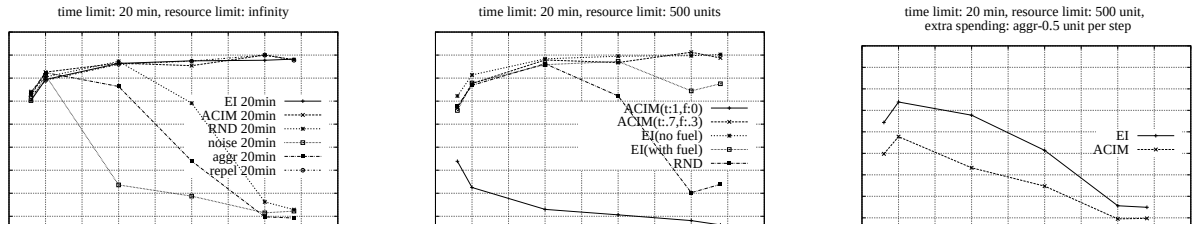
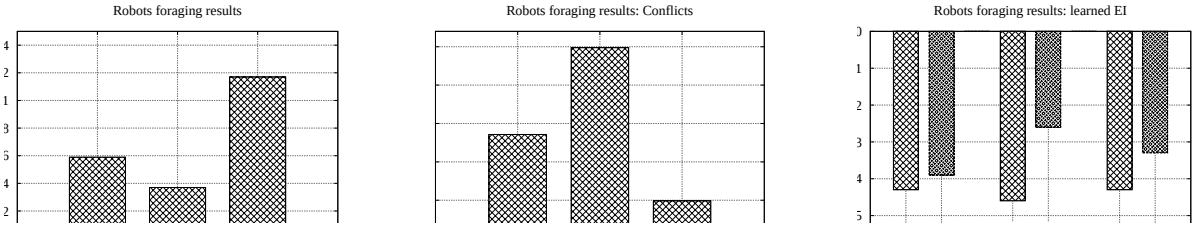
5. WHY DOES EI WORK?



(a) $T = 20$, no resource limits. (b) $T = 20$, severe fuel limits. (c) $T = 20$, resource cost unknown.

Figure 2: Results from the TeamBots foraging domain.



(a) Pucks collected per minute (median). (b) Mean number of conflicts (lower result is better). (c) Negative EI values for Noise and Repel in the three robots (higher is better).

Figure 4: Results from the AIBO foraging domain.

We now turn to discuss the use of EI as a reward function, from an analytical perspective. We are interested in exploring the conditions under-which we expect EI to be effective. There are common themes that run through all the tasks in which EI has been successful: (i) loose coordination between the robots (i.e., only occasional need for spatial coordination); (ii) a cooperative task (the robots seek to maximize group utility); and (iii) the task is bound in time. We refer to these tasks as *LCT tasks* (Loose-coordination, Cooperative, Timed tasks).

For instance, in foraging, we see that robots execute their individual roles (seeking pucks and retrieving them) essentially without any a-priori coordination. When they become too close to each other, they need to spatially coordinate. The robot all contribute to the team goal, of maximizing the number of pucks retrieved. Moreover, they have limited time to do this. Incidentally, they also have finite number of pucks, which break some of the assumptions we make below. We shall come back to this.

Computing optimal plans of execution for tasks such as foraging is purely a theoretical exercise in the current state of the art. In practice, determining detailed trajectories for multiple robots in continuous space, with all of the uncertainties involved (e.g., pucks slipping from robots' grips, motion and sensing uncertainty), is infeasible. Much more so, when we add the a-priori selection of coordination methods in different points in time. We therefore seek alternative models with which to analytically explore LCT tasks.

5.1 LCT Tasks as Extensive-Form Games

We turn to game theory to represent LCT tasks. As we have already noted, each individual robot's perspective is that its task execution is occasionally interrupted, requiring the application of some coordination method in order to resolve a spatial conflict, to get back to task execution. Assume for simplicity of the discussion that we limit ourselves to two robots, and that whenever they are in conflict, they are both aware of it, and they both enter the conflict at the same time. This is a strong assumption, as in actuality, most often LCT tasks often involve more than two robots. We address this assumption later in this section.

At first glance, it may seem possible to model LCT tasks as a series of single-shot games (i.e., repeating games), where in each game the actions available to each robot consist of the coordination methods available to it. The joint selection of methods by the two robots creates a combination of methods which solves the conflict (at least temporarily). The payoffs for the two robots include the pucks collected in the time between games, minus the cost of resources (including time) spent making and executing the selected methods. The fact that there exists a time limit to the LCT task in question can be modeled as a given finite horizon.

However, finite-horizon repeating games are not a good model for LCT tasks. In particular, the methods selected by the robots in one point in time affect the payoffs (and costs) at a later point in time. First, the choice of coordination methods at time t affects the time of the next conflict. One coordination method may be very costly, yet reduce the likelihood that the robots get into conflict again; another method may be cheap, but cause the robots to come into conflict often. Second, the robots change the environment in which they operate during the time they are carrying out their tasks, and thus change future payoffs. For instance, robots collect pucks during their task execution time, and often collect those nearest the goal area first. Thus their payoff (in terms of pucks collected) from games later in the sequence is lower than from games earlier on.

We thus utilize a model of LCT tasks as extensive-form games. The initial node of the game tree lies at the time of the first conflict, $c_{i,1}$, and the choices of the first robot at this time lead to children of this node. As the two robots act simultaneously, these children also occur at time $c_{i,1}$. Also, note that the selections of the robots are not observable to each other[1]. An illustration of the game tree

[1]This is true in all communication-less coordination methods, which are used in most previous work [20, 17]. When used with communication-based coordination method, this restriction may be removed. It might also be possible to relax this restriction if robots

appears in Figure 6.

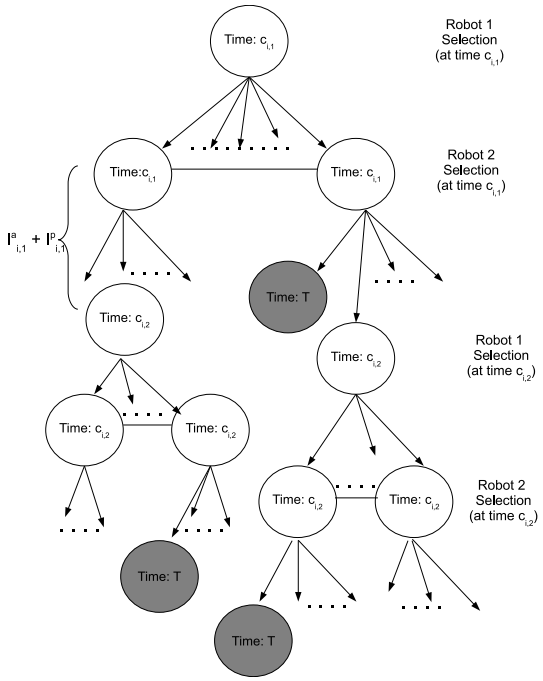


Figure 6: An illustration of the extensive-form game tree for an LCT task. Conflict times are denoted in the nodes. Terminal nodes (total time=T) are dark. Note that the second conflict $c_{i,2}$ may occur at different absolute times depending on the choices of the robots at time $c_{i,1}$.

Following each simultaneous choice of methods by the robots, the chosen combination of coordination methods is executed (during coordination time $I^a_{i,j}$), and this is followed by a period of task execution $I^p_{i,j}$. The game ends when total time T runs out. The payoffs to the robots are then given as the number of pucks retrieved, minus the cost of resources spent on the task. Terminal nodes may appear anywhere in the game tree, as some selections of the robots lead to less conflicts, and thus greater opportunity for task execution.

Under ideal—and purely theoretical conditions—the robots would know the payoffs awaiting them in each terminal node, and would thus be able to, in principle, compute a game-playing strategy that would maximize the team's utility. To do this, the robots would need to know the times spent resolving conflicts and executing the task, and would also need to know (in advance) the gains achieved during each task-execution period. Even ignoring the gains, and assuming that maximizing task-execution time $\sum_i \sum_j I^p_{i,j}$ is sufficient, the robots would be required to know all conflict resolution times in advance. This is clearly impractical, as it requires predicting in advance all possible conflicts and their durations and effects. And the sheer size of the game tree (there are hundreds of conflicts in a typical foraging task, as presented in the previous section) makes learning it a difficult task at best. We are not aware of any method capable of learning the terminal payoffs or node-associated durations and effects for the type of domains we study in this paper.

5.2 Modeling LCT Tasks as a Matrix Game

We thus make a simplifying assumption, that all effects of coordination method selections remain fixed, regardless of where they occur. In other words, we assume that the joint execution of a specific combination of selected coordination methods will always cost the same (in time and resources), regardless of the time in which the conflict occurred. Moreover, the assumption also implies that we assume that the task-execution time (and associated gains)—which depends on the methods selected—will also remain fixed. We state this formally:

Assumption 1. Let α be a coordination method, selected by robot i. We assume that for any $0 \leq j,k \leq K_i$, the following hold:

$$I^a_{i,j}(\alpha) = I^a_{i,k}(\alpha), \quad I^p_{i,j}(\alpha) = I^p_{i,k}(\alpha), \quad C^C_{i,j}(\alpha) = C^C_{i,k}(\alpha)$$

This strong assumption achieves a key reduction in the complexity of the model, but gets us farther from the reality of LCT multi-robot tasks. However, the resulting model provides an intuition as to why and when EI works. In Section 5.4 we examine the assumptions of the model and their relation to the reality of the experiments.

The duration of coordination method execution (I^a_i), and the duration of the subsequent conflict-free task-execution (I^p_i), are fixed; they now depend only on the method selected, rather than also on the time of the selection. Thus a path through the game tree can now be compressed. For each combination of selected coordination method, we can simply multiply the costs and gains from using this combination, by the number of conflicts that will take place if it is selected.

Thus we can reduce the game tree into a matrix game, where $K_{i,j}$ is the number of conflicts occurring within total time T that results from the first robot selecting α_i, and the second robot selecting α_j. $U_{i,j}$ is the utility gained from this choice. This utility is defined as:

$$\begin{aligned} U_{i,j} \equiv \; & [gain(I^p_i(\alpha_i)) + gain(I^p_j(\alpha_j))] \\ & - [C^C_i(\alpha_i) + C^C_j(\alpha_j)] \end{aligned} \tag{4}$$

where we use (for robot i) the notation $gain(I^p_i(\alpha_i))$ to denote the gains achieved by robot i during the task execution time $I^p_i(\alpha_i)$. Note that we treat these gains as being a function of a time duration only, rather than the method α, which only affect the time duration. Underlying this is an assumption that the coordination method choice affect utility (e.g., the pucks acquired) only indirectly, by affecting the time available for task execution. We assume further that gains monotonically increase with time. Maximizing the time available, maximizes the gains.

Table 1 is an example matrix game for two robots, each selecting between two coordination methods. Note however that in general, there are N robots and $|M|$ methods available to each.

	α^2_1	α^2_2
α^1_1	$K_{1,1}U_{1,1}$	$K_{1,2}U_{1,2}$
α^1_2	$K_{2,1}U_{2,1}$	$K_{2,2}U_{2,2}$

Table 1: LCT task as a matrix game, reduced from the LCT game tree by Assumption 1. Entries hold team payoffs.

Note that the robots do not have access to the selections of the other robots, and thus for them, the game matrix does not have a single common payoff, but individual payoffs. These are represented in each cell by rewriting $K_{i,j}U_{i,j}$ as $K_{i,j}u_i(\alpha_i), K_{i,j}u_j(\alpha_j)$, where

$$u_k(\alpha_k) \equiv gain(I^p_k(\alpha_k)) - C^C_k(\alpha_k).$$

This results in the revised matrix game appearing in Table 2.

The number of conflicts $K_{i,j}$ is really the total time T, divided by the duration of each conflict cycle, i.e., $I^a + I^p$. Thus the individual payoff entries for robot l selecting method k can be rewritten as $\frac{T}{I^a_l(\alpha_k)+I^p_l(\alpha_k)}u_l$.

could infer each others' choices post-factum.

	α_1^2	α_2^2
α_1^1	$K^1_{1,1}u_1(\alpha_1^1), K^2_{1,1}u_1(\alpha_1^2)$	$K^1_{1,2}u_1(\alpha_1^1), K^2_{1,2}u_2(\alpha_2^2)$
α_2^1	$K^1_{2,1}u_2(\alpha_2^1), K^2_{2,1}u_1(\alpha_1^2)$	$K^1_{2,2}u_2(\alpha_2^1), K^2_{2,2}u_2(\alpha_2^2)$

Table 2: An example LCT task as a matrix game, with individual payoffs.

Let us now consider these individual payoffs. The payoff for an individual robot l which selected α is:

$$\frac{T[g(I_l^p(\alpha)) - c(I_l^a(\alpha))]}{I_l^a(\alpha) + I_l^p(\alpha)} \propto \frac{g(I_l^p(\alpha)) - c(I_l^a(\alpha))}{I_l^a(\alpha) + I_l^p(\alpha)} \quad (5)$$

$$\propto \frac{I_l^p(\alpha) - c(I_l^a(\alpha))}{I_l^a(\alpha) + I_l^p(\alpha)} \quad (6)$$

These two steps require some explanation. First, of course, since for all entries in the matrix T is constant, dividing by T maintains the proportionality. The second step is key to the EI heuristic. It holds only under certain restrictions on the nature of the function $gain()$, but we believe these restrictions hold for many gain functions in practice. For instance, the step holds whenever $gain()$ is linear with a coefficient greater than 1. Now:

$$\frac{I_l^p(\alpha) - c(I_l^a(\alpha))}{I_l^a(\alpha) + I_l^p(\alpha)} = \frac{I_l^p(\alpha) + [I_l^a(\alpha) - I_l^a(\alpha)] - c(I_l^a(\alpha))}{I_l^a(\alpha) + I_l^p(\alpha)} \quad (7)$$

$$= \frac{[I_l^p(\alpha) + I_l^a(\alpha)] - [I_l^a(\alpha) + c(I_l^a(\alpha))]}{I_l^a(\alpha) + I_l^p(\alpha)} \quad (8)$$

$$= \frac{I_l^p(\alpha) + I_l^a(\alpha)}{I_l^p(\alpha) + I_l^a(\alpha)} - \frac{I_l^a(\alpha) + c(I_l^a(\alpha))}{I_l^a(\alpha) + I_l^p(\alpha)} \quad (9)$$

$$= 1 - EI_l(\alpha) \quad (10)$$

$$\propto -EI_l(\alpha) \quad (11)$$

Thus the game matrix is in fact equivalent to the following matrix (Table 3). Here, each robot seeks to minimize its own individual EI payoff (maximize its -EI payoff). If robots minimize their individual EI payoffs, and assuming that their equilibrium is Hicks optimal (i.e., the sum of payoffs is maximal), then solving this game matrix is equivalent to maximizing group utility.

	α_1^2	α_2^2
α_1^1	$-EI_1(\alpha_1^1), -EI_2(\alpha_1^2)$	$-EI_1(\alpha_1^1), -EI_2(\alpha_2^2)$
α_2^1	$-EI_1(\alpha_2^1), -EI_2(\alpha_1^2)$	$-EI_2(\alpha_2^1), -EI(\alpha_2^2)$

Table 3: LCT task as an EI matrix game.

5.3 Learning Payoffs in LCT Matrix Games

Unfortunately, when the robots first begin their task, they do not know the payoffs, and thus rely on the reinforcement learning framework to converge to appropriate EI values. Of course, it is known that Q-learning does not, in the general case, converge to equilibrium in 2-player repeated games [4, 23, 10]. However, there are a number of features that hold for the EI game matrix *in the domains we study*, which makes the specific situation special.

First, the game matrix is theoretically symmetric. Because robots are homogeneous, a combination of coordination methods $\langle \alpha_1, \alpha_2 \rangle$ will yield the same payoffs as $\langle \alpha_2, \alpha_1 \rangle$.

Second, we know that for the specific game settings, one combination yields optimal payoffs (in the sense that the sum of robot payoffs is optimal). Although it is now accepted that no one coordination method is always best in all settings, it is certainly the case that in a specific scenario (e.g., a specific group size), a combination can be found which is best.

Third, the value of EI for the optimal individually-selected method α_j^1 can only decrease if the other robot does not select an optimal method α_k^2. Under normal conditions, the numerator of the EI value, $I_1^a(\alpha_j^1) + C^C(\alpha_j^1)$ is dependent only on the execution of α_j^1 by the robot. On the other hand, the denominator $I_1^a(\alpha_j^1) + I_1^p(\alpha_j^1)$ can only decrease (because the time to the next conflict, $I_1^p(\alpha_j^1)$ can only decrease, by definition). Thus, the EI value can only grow larger (i.e., $-EI$ grows smaller). Selection of the optimal EI values is thus dominant.

Finally, and most importantly, the games that take place here are *not* between two players. Rather, the process is more akin to randomized anonymous matching in economics and evolutionary game theory. In this process, pairs of players are randomly selected, and they do not know their opponents' identity (and thus do not know whether they have met the same opponents before).

Indeed, this last quality is crucial in understanding why our use of EI works. It turns out that there exists work in economics that shows that under such settings, using simple reinforcement learning techniques (in our case, stateless Q-learning) causes *the population* to converge to Nash equilibrium, even if mixed [11]. Thus rather than having any individual agent converge to the mixed Nash equilibrium, the population as a whole converges to it, i.e., the number of agents selecting a specific policy is proportional to their target probabilities under the mixed Nash equilibrium.

There remains the question of why do agents converge to the maximal payoff Nash equilibrium. We again turn to economics literature, which shows that for coordination games—including even the difficult Prisoner's Dilemma game—agents in repeated randomized matching settings tend to converge to the Pareto-efficient solution [5, 16]. However, these works typically assume public knowledge of some kind, which is absent in our domain. Thus we leave this as a conjecture.

5.4 Revisiting the EI Experiments

Armed with the analytically-motivated intuition as to why EI works, we now go back to re-examine the experiment results. In general, there are of course differences between the analytical intuitions and assumptions and the use of EI in a reinforcement learning context: (i) the values learned our approximations of the EI values, which cannot be known with certainty; (ii) the assumptions allowing reduction of the LCT extensive-form game tree to a game matrix do not hold in practice; and (iii) even the assumptions underlying the extensive-form game tree (e.g., that robots start their conflict at the same time, or that their gains depend only on time available for task execution) are incorrect. We examine specific lessons below.

We begin with the teambots simulation experiments, where EI was highly successful, and was also demonstrated to be robust to unknown costs. Despite the fact that the domain cannot be reduced to the matrix game form, it turns out that some of the assumptions are approximately satisfied, which explain the success of EI here.

First, the fact that about half the pucks moved randomly helped spread them around the arena even after many pucks were collected. Thus the gains expected later in the task were closer to the gains at the beginning to the task, than it would have been had all pucks been immobile (in which case pucks closer to base are collected first, resulting in higher productivity in the beginning).

Second, the size of the arena, compared to the size of the robots, was such that the robots did not need to converge to one optimal combination of selection methods: Different zones in the arena required different combinations. In principle, this should have chal-

lenged the approach, as the stateless learning algorithm cannot reason about the robots being in different states (zones). However, as the robots moved between areas fairly slowly, they were able to adapt to the conditions in new zones, essentially forgetting earlier EI values. This is a benefit of the stateless algorithm.

The use of the fixed exploration rate can hurt performance of the algorithm, as is clearly seen in the results of the AIBO foraging experiments. Because robots *must* explore, they are sometimes forced to act against their better knowledge, and thus reduce performance. But this did not affect the results in the simulation domain, where EI often gave the best results of all methods. We believe that this is due to the size of the arena, which created different zones as discussed above. Here exploration was very useful, to enable implicit transition between states. In contrast, in the AIBO experiments, the size of the arena was so small, that density remained fixed throughout the arena, and exploration eventually lead to reduced results.

An interesting lesson can be learned from the experiments in the virtual environment. Here, EI was applied to a task that it was not meant for, involving implicit, rather than explicit, coordination. The nature of this task was that not one single equilibrium point existed, as one combination of paths works always (i.e., a mixed Nash equilibrium). Indeed, the algorithm converged quickly to selecting between two almost equally-valued alternatives, reflecting the two top choices.

6. SUMMARY

This paper examined in depth a novel reward function for cooperative settings, called Effectiveness Index (EI). EI estimates the resource spending velocity of a robot, due to its efforts spent on coordination. By minimizing EI, robots dedicate more time to the task, and are thus capable of improving their team utility. We used EI as a reward function for selecting between coordination methods, by reinforcement-learning. This technique was shown to work well in three different domains: Simulation-based multi-robot foraging, real AIBO multi-robot foraging, and high-fidelity commercial virtual environment. The experiments explore the scope of the technique, its successes and limitations. In addition, we have formally explored multi-robot tasks for which EI is intended. We have shown that under some assumptions, EI emerges analytically from a game-theoretic look at the coordination in these tasks. We believe that this work represents a step towards bridging the gap between theoretical investigations of interactions, and their use to inform real-world multi-robot system design. Improved results can be achieved by extending both the theory underlying the use of EI, and the learning algorithms in which it is used.

Acknowledgements. We thank Dov Miron and Shai Shlomai for their assistance with the AIBO experiments.
